# Extracerebral Collections: Recognition by NMR Imaging

I. R. Young,<sup>1</sup> G. M. Bydder,<sup>2</sup> A. S. Hall,<sup>1</sup> R. E. Steiner,<sup>2</sup> B. S. Worthington,<sup>3</sup> R. C. Hawkes,<sup>4,5</sup> G. N. Holland,<sup>4</sup> and W. S. Moore<sup>4</sup>

After head injury, nuclear magnetic resonance (NMR) scanning is, like computed tomography (CT), an effective method of distinguishing between intracerebral and extracerebral lesions. The location and shape of extracerebral collections are excellently displayed using the multiplanar facility of NMR. There are good grounds for believing that the problem of the isodense subdural hematoma encountered in CT scanning can almost certainly be overcome by the use of NMR imaging.

Cranial trauma accounts for as many as 10% of all patients seen in British accident and emergency departments. In the acute phase, deterioration in the level of consciousness with or without focal neurologic signs is the chief indication for radiologic investigation, and for this computed tomography (CT) has completely superseded angiography [1]. Extracerebral collections are the most common treatable lesions that can be demonstrated. Scans will also show the compression of the underlying brain and the presence of associated contusion or hematoma, the greater the degree of which the less favorable the prognosis [2]. Although there is no strict correlation between the age of a hematoma and its density, there is a general decrease with time such that hematomas pass through a stage (typically 2–4 weeks after injury) when they are isodense with brain [3]. Diagnosis then may be very difficult and often depends on the observation of indirect signs in unilateral collections. These include midline shift, flattening of the ipsilateral ventricle, effacement of cortical sulci, and medial displacement of the gray-/white-matter interface [4]. In bilateral collections there are compression of the ventricles and effacement of the basal cisterns and cortical sulci. Care must be taken here not to confuse hypodense collections with cerebral atrophy.

## Methods and Results

In the University Hospital, Nottingham, and the Hammersmith Hospital, London, we have had the opportunity to study several patients with extracerebral collections using a variety of different nuclear magnetic resonance (NMR) scanning sequences. Whether intracerebral or extracerebral, an acute hematoma appears white on both inversion-recovery,  $T_1$ -dominated images, and  $T_2$  spin-echo images. This is because it displays a short  $T_1$  value while showing an increased  $T_2$  value relative to normal brain. On  $T_1$ -dominated images contusion and edema are associated with a long  $T_1$  value

Fig. 1.—Axial transverse (A) and coronal (B) (SSFP) NMR scans showing high-convexity subdural hematoma.

Fig. 2.—CT scan (A) and spin-echo NMR scan (B) of subdural hematoma. Collection is hypodense on CT and is better seen on NMR scan, reflecting long  $T_2$  time of clotted blood. Periventricular edema is also known.

and thus appear black, allowing a clear distinction to be made from hematoma. On  $T_2$ -dominated images both hematoma and contusion lead to a lengthening of  $T_2$  and so cannot be distinguished. In the transverse CT scan shown in figure 1A a hypodense subdural collection is seen over the high convexity and is associated with ventricular compression and medial displacement of the gray-/white-matter interface, a feature that will be more clearly seen on  $T_1$ -dominated images. The hematoma is very well seen on the  $T_2$ -dominated image together with periventricular edema (fig. 2B). Both in acute extracerebral collections (which have a higher CT attenuation value than brain) and in hypodense collections (with a lower attenuation value than brain), there is a high signal on the  $T_2$ -dominated image. We may therefore infer that even during the transitional period, when the attenuation value of a collection changes and it becomes isodense, it will nevertheless give a higher signal than brain on the NMR scan.

### Discussion

Because the changes in the spin relaxation times associated with clotted blood are in the opposite sense—that is, a short  $T_1$  and long  $T_2$ —the ratio  $T_2/T_1$  greatly increased. This makes steady-state free-precession sequences (SSFP), which reflect this ratio, exquisitely sensitive to the presence of hematoma. The transverse and coronal sections (fig. 1) of a convex hematoma that was isodense on CT illustrate this, and also show the value of the multiplanar facility of NMR for defining the full extent of a collection. This will be particularly valuable in extensions beneath the temporal lobe

and in collections situated under the tentorium. Arachnoid malformations occur in many sites but they are most common in the middle cranial fossa [5] (fig. 3). The SSFP NMR scans show a low-density area within the expanded middle cranial fossa. The density corresponds to the long  $T_1$  value of its contents, which approaches that of cerebrospinal fluid.

It appears that NMR will be more sensitive than CT in the detection of extracerebral collections because the isodense lesion will not be a problem. Its ability to demonstrate parenchymal damage and hematoma also commend its sequential use in patients who fail to improve or who deteriorate after a head injury. Repeated examination can be valuable in monitoring the effects of treatment.
